Making sense of the hairball is hard

Amplicon / metagenomic surveys → **co-occurrence networks**: thousands of **undirected** edges between taxa that appear together (or avoid each other).

How do we make **sense** out of the hairball?

A co-occurrence network in Cytoscape

microbetag: a hypothesis generator

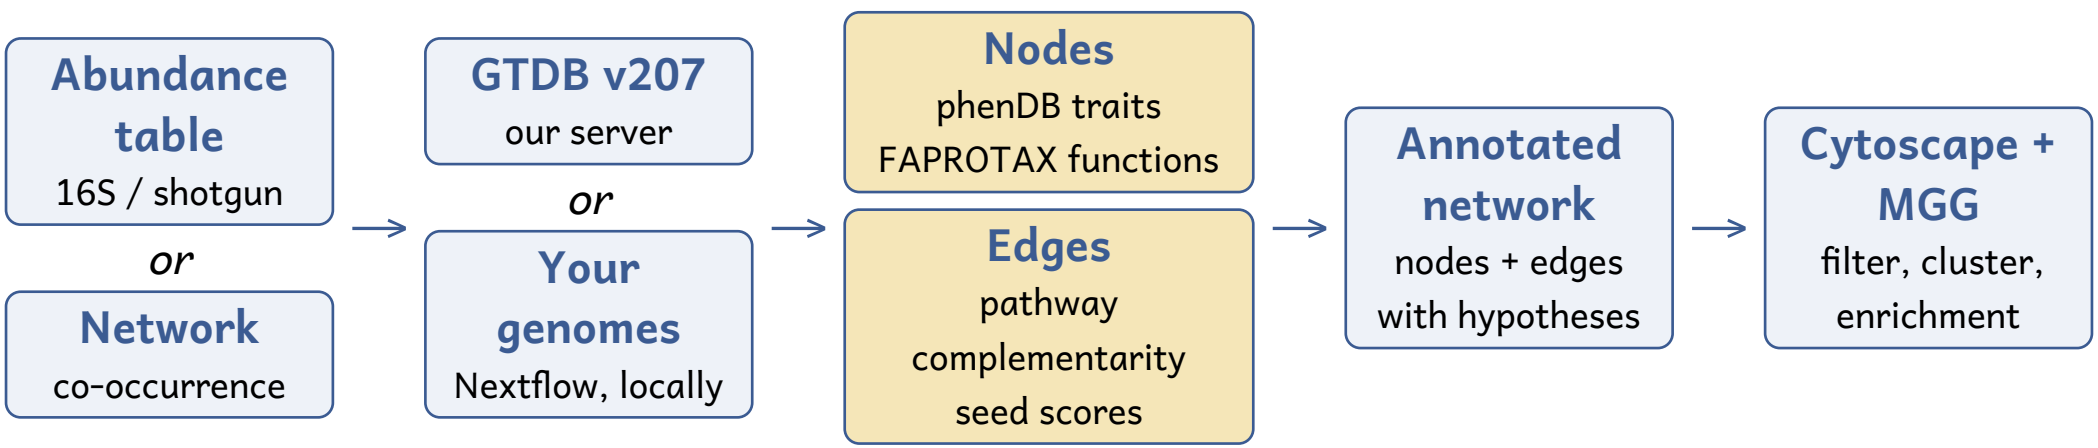

We cannot prove interactions from co-occurrence / mutual exclusion alone, but genomes can suggest **why** two taxa show such a pattern:

- *complementary* pathways → **cross-feedings**?
- overlapping needs → **competition**?
- shared traits → same **niche**?

▹ microbetag

Turns the hairball into **testable hypotheses**

How microbetag works

Node level: what are a species' phenotypic traits?

Each taxon gets **functional traits**: genome-based predictions (phenotrex) and literature-based **FAPROTAX** functions (105 in total), e.g.:

▹ Carbon

- methanogenesis
- fermentation
- cellulolysis

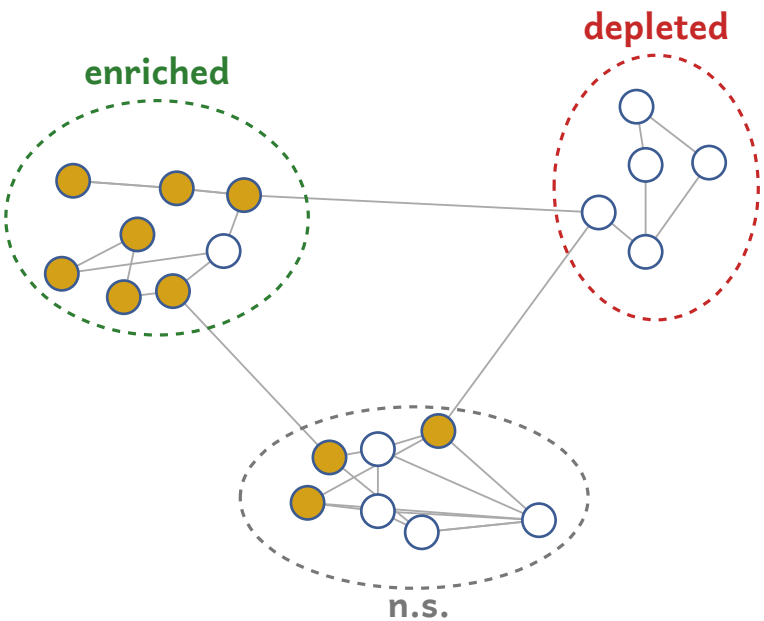

▹ Nitrogen & sulfur

- nitrogen fixation
- denitrification
- sulfate respiration

▹ Lifestyle

- obligate anaerobes
- human gut
- plant pathogen

Clusters & enrichment *analysis*

- taxon **with** the trait
- taxon **without**

1. **Cluster** the network (e.g. manta)
2. Per cluster & trait: **hypergeometric test** (wiki)
3. FDR correction → **enriched** / **depleted**

Each cluster reads as a **functional guild**

Edge level: what could they exchange?

▹ Pathway complementarity

KEGG modules one taxon misses and its partner can complete

▹ Seed scores

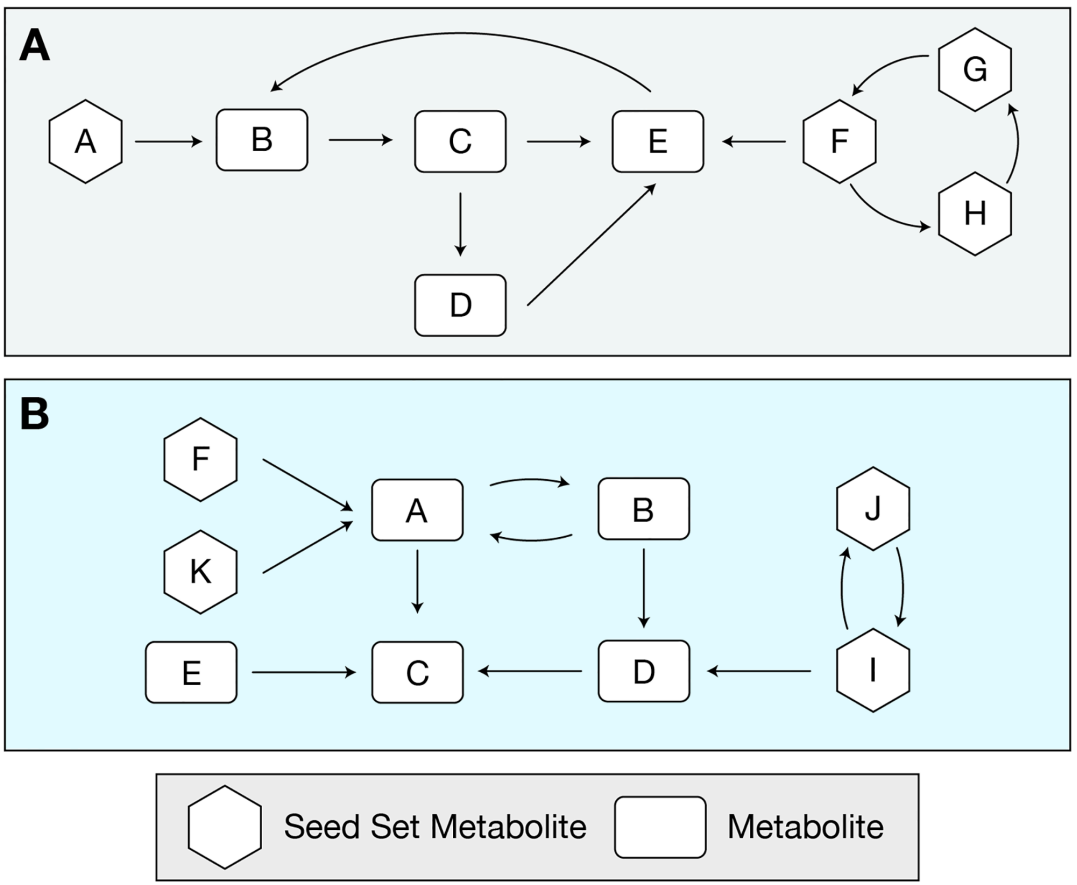

Competition and cooperation potential from metabolic network seed sets

▹ Seed complementarity

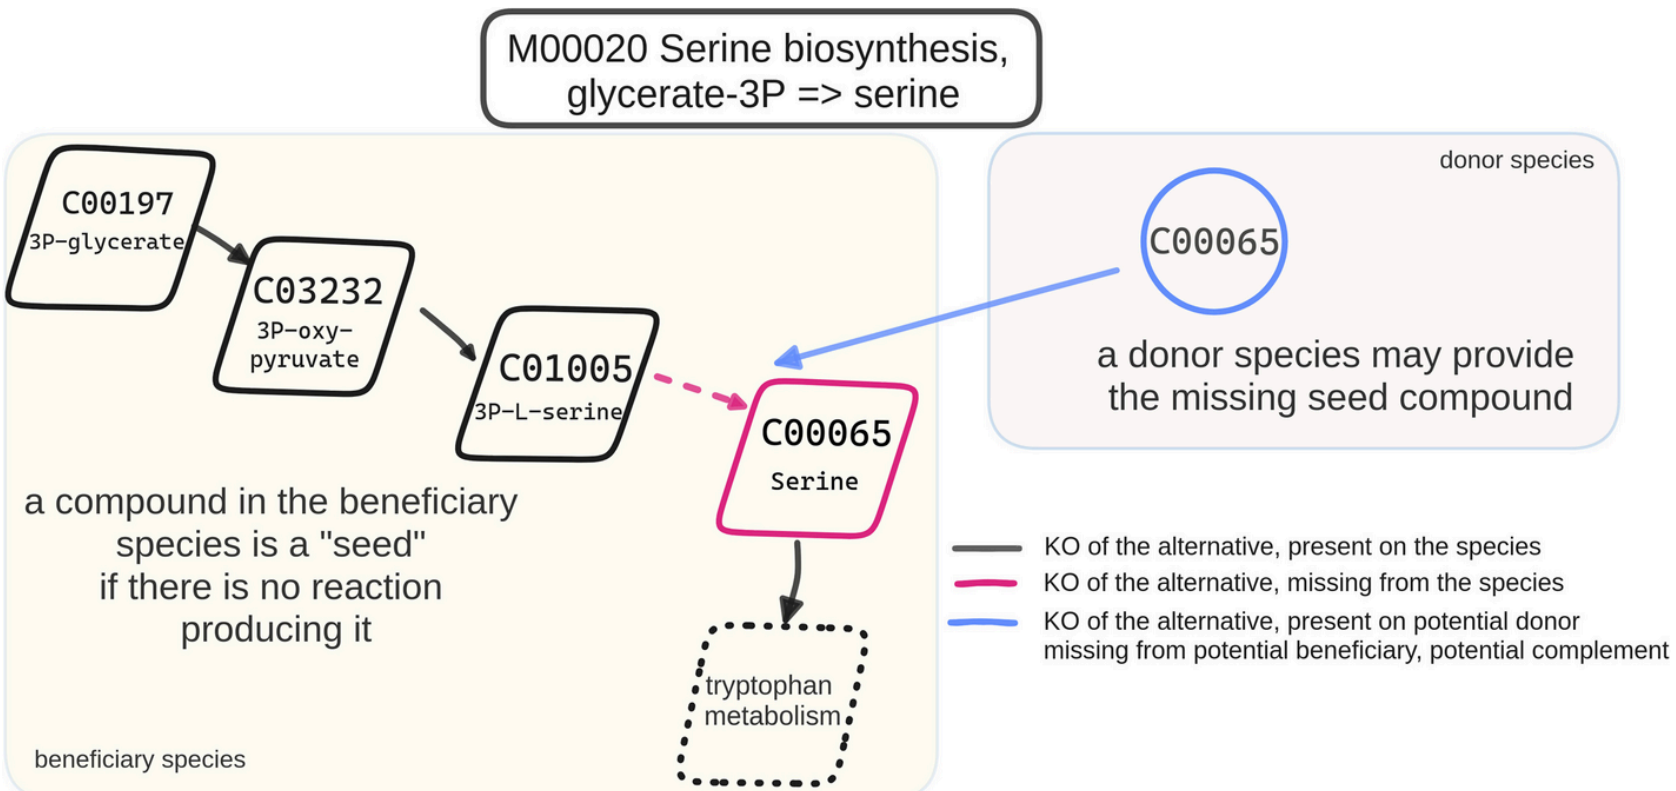

Candidate exchanged compounds from genome-scale models

The seed concept

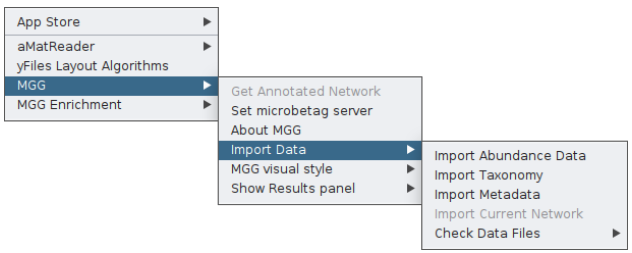

Pseudo metabolitc networks of species A and B

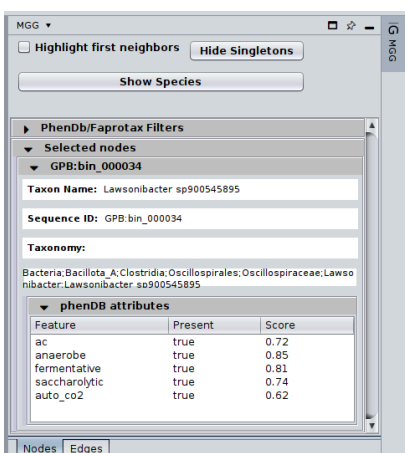

Seed complementarity

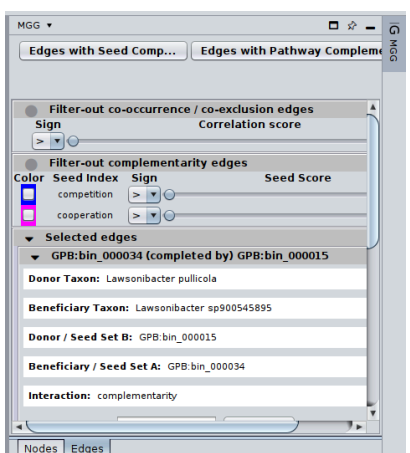

Parsing the network with MGG

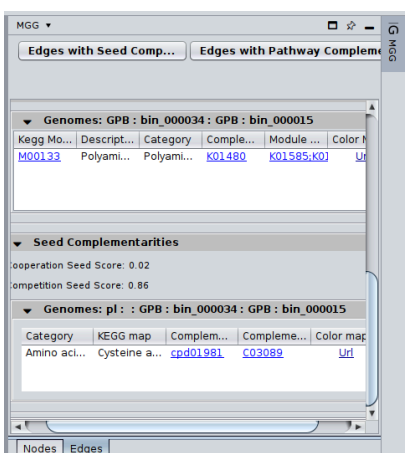

1. **Import** abundance table, taxonomy, metadata
2. **Get annotated network** from our server, or import your local one
3. Click *a* **node** or **edge** to read its annotations, **filter** edges by correlation or seed scores
4. Run **MGG Enrichment** on clusters

Nodes: taxonomy, phenDB / FAPROTAX

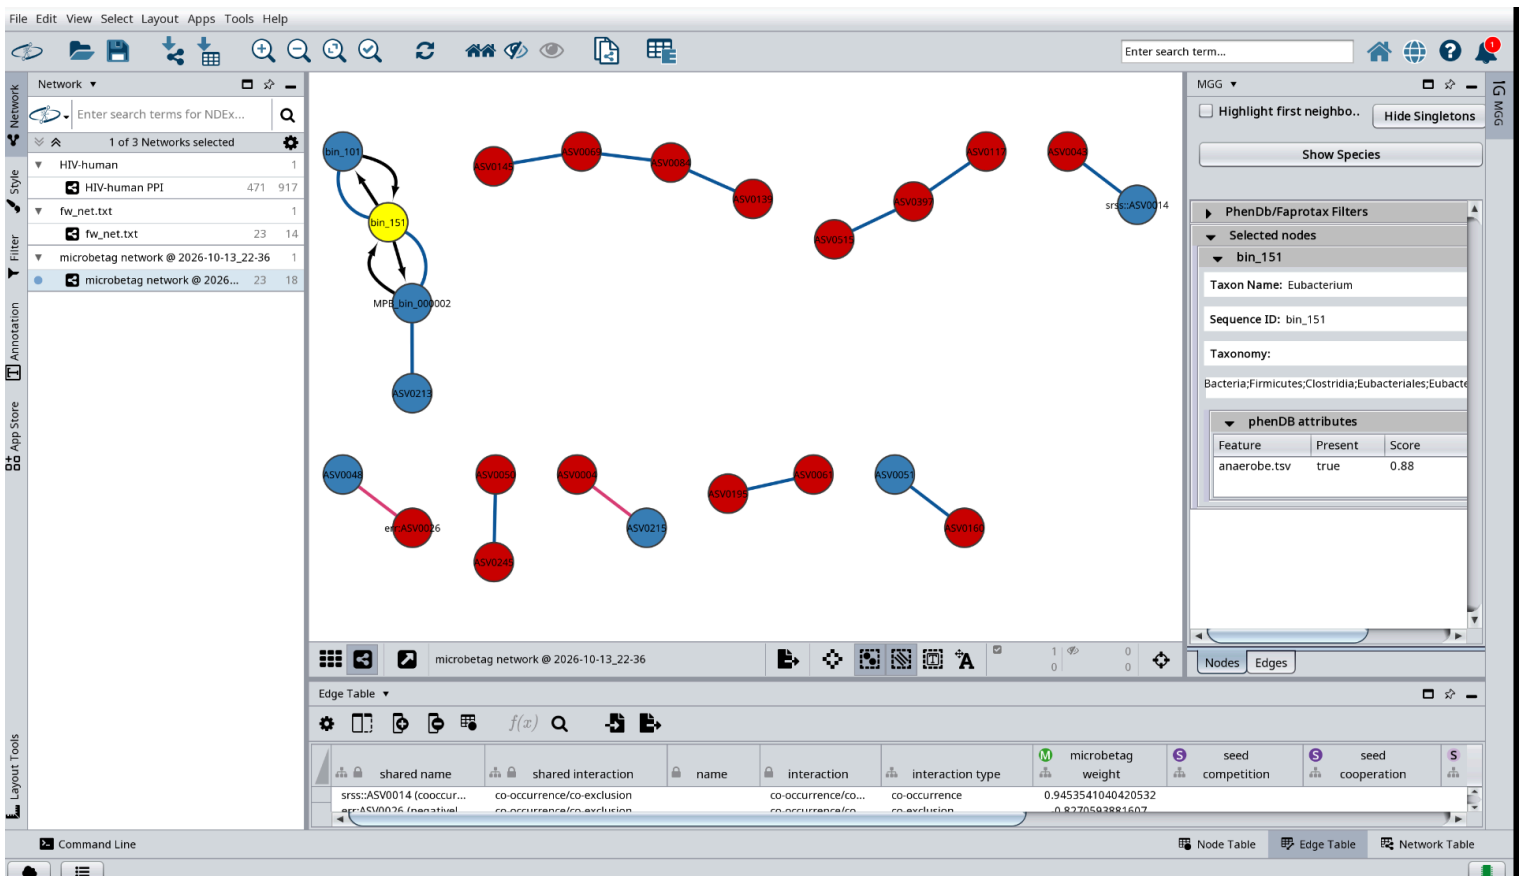

Edges: filters, donor → beneficiary

Edges: KEGG modules, seed scores

An annotated network in Cytoscape

Two ways to run microbetag

▹ On our server

- Against **GTDB v207** genomes
- Submit your **abundance table** or **network** through the MGG Cytoscape app
- Results come back as an annotated network

▹ Locally, with your genomes

- New: **Nextflow** pipeline
- Use your own genomes / MAGs
- Import the annotated network into Cytoscape with MGG

Either way: explore, filter and cluster the annotated network in **Cytoscape**.

microbetag.readthedocs.io · github.com/msysbio/microbetag

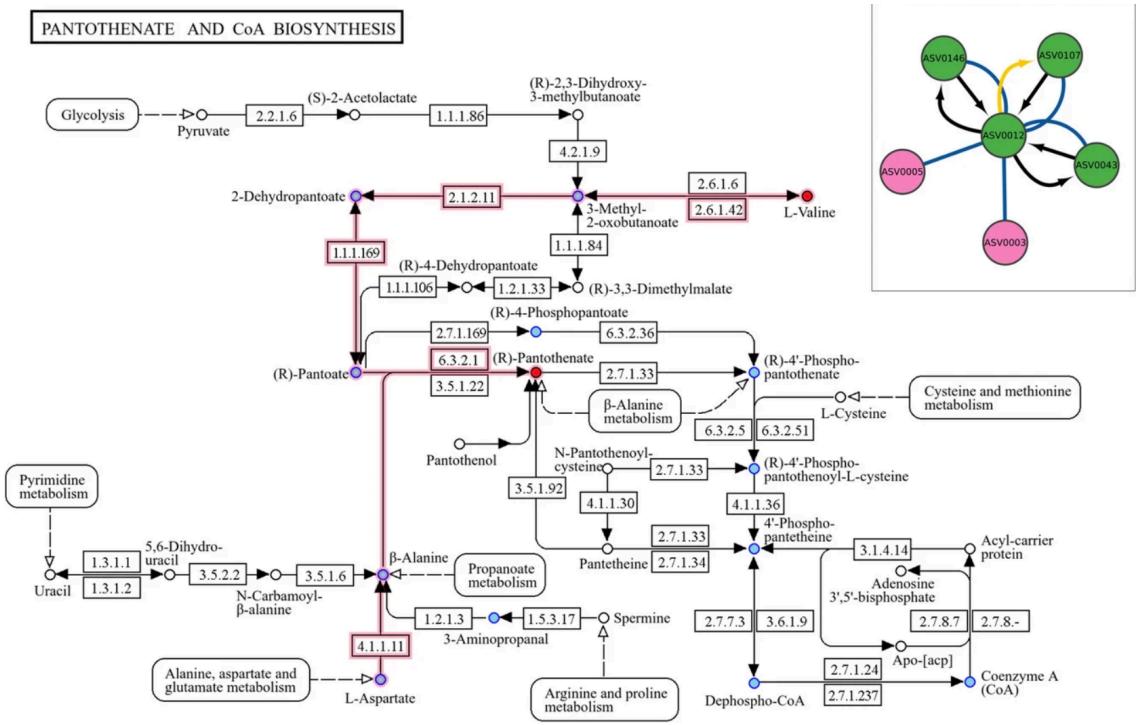

Case study: infant gut

Cabrera *et al.* (2019)
iron supplementation in infants

E. lenta → *F. plautii*
ASV0107 donor ASV0012 beneficiary

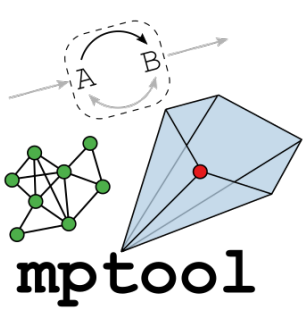

Complements: L-valine, (R)-pantothenate
→ vitamin B5 → **coenzyme A**

Hypothesis: FOS boosts butyrate & *Flavonifractor* partly via **cross-feeding partners**

Limits — and what's next

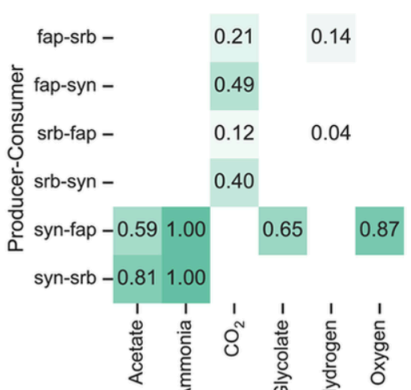

- Hypotheses, not proof: needs experimental validation
- Inherits the network's biases (depth, rare taxa, scale)
- Genome coverage: unmapped taxa stay unannotated
- Next: **interactions' dynamics** — do predicted interactions show up under different media ?

+

→

Take-home

▹ microbetag

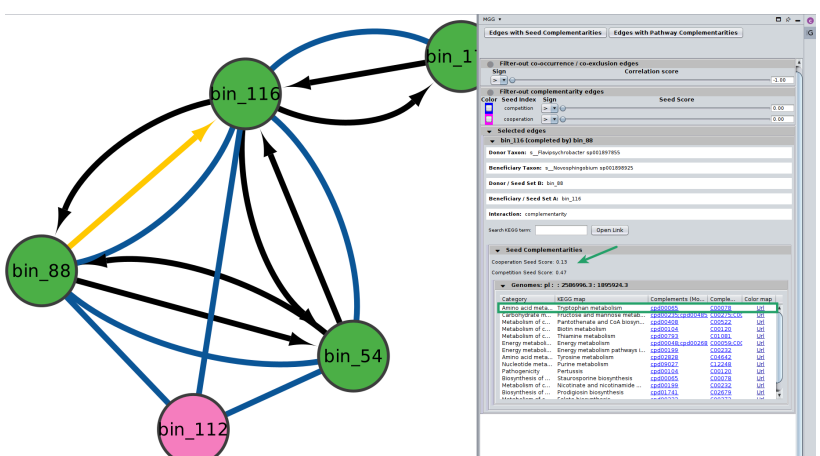

Makes sense of the hairball: from **who is with whom** to testable hypotheses of **what they do and exchange**.

Challenges in co-occurrence inference

1. **Sequencing depth** varies across samples → compositional artefacts
2. **Rare taxa** → sparse counts, unstable correlations
3. **Indirect edges** → A–C may only reflect A–B and B–C; correlation ≠ interaction
4. **Undirected edges** → who affects whom? an edge has no direction
5. **Sampling scale** → interactions happen at the **microscale**, but we sample at the **macroscale**

Sampling scale

Technical variability.
Read count ≠ cell count

Compositionality
